Dividend problems for a Lévy insurance risk process

Zbigniew Palmowski

Joint work with F. Avram, S. Baran, I. Czarna, A. Kyprianou, M. Pistorius
The word *dividend* comes from the Latin word *dividendum* meaning *the thing which is to be divided* and has got sense of *portion of interest on a loan, stock, etc.*

Dividends are usually defined as the distribution of earnings in real assets among the shareholders of the firm (in proportion to their ownership).

Dividends are paid from the firm’s after-tax income. For the recipient, dividends are considered regular income and are therefore fully taxable.

There are two sides of dividends policies in the modern corporate firms. The first are managers of the firm (insiders), the second are shareholders (outsiders). The interest of management and shareholders may not coincide. This has important consequences for dividend policy. There is a suggestion that former typically prefer a low payout in order to pursue growth maximizing strategies or consume additional benefits, while letters generally wish for a high payout since this will force the management to incur the inspection of the capital markets for each new project undertaken.

We focus in this talk on the maximizing the cumulant dividend payments (we look at it only from the point of view of beneficiaries).
Usually the surplus $X = \{X_t, t \geq 0\}$ of an insurance company is described by Cramér-Lundberg process:

$$X_t = x + pt - \sum_{k=1}^{N_t} C_k$$

where

$C_k$ - i.i.d. claims with d.f. $F$

$N_t$ - independent Poisson process with intensity $\lambda$

$p$ - premium rate

For a classical risk process many optimal problems mentioned during this talk are analyzed in:

Hanspeter Schmidli

Stochastic Control in Insurance

$X_t$ - spectrally negative Lévy process which is not subordinator

will model reserves of insurance company (in the absence of dividend payments), that is:

$X_t$ - process with independent and stationary increments \textit{without} positive jumps
$X_t$ - spectrally negative Lévy process which is not subordinator

will model reserves of insurance company (in the absence of dividend payments), that is:

$X_t$ - process with independent and stationary increments without positive jumps

Lévy-Khinchine formula:

$$E e^{i\theta X_t} = e^{-\Psi(\theta)t}$$

where

$$\Psi(\theta) = -i\rho\theta + \frac{\sigma^2}{2}\theta^2 + \int_{(-\infty,-1)} (1 - e^{i\theta x}) \Pi_X(dx)$$

$$+ \int_{(-1,0)} (1 - e^{i\theta x} + i\theta x) \Pi_X(dx)$$

and we assume that $\int_{(-1,0)} (1 \wedge x^2) \Pi_X(dx) < \infty$
Let assume that $X_t \rightarrow \infty$ a.s.
Let assume that $X_t \to \infty$ a.s.

Controlled process:

$$U^\pi_t = X_t - D^\pi_t$$

where $D^\pi_t$ denotes cumulative amount of dividends transferred up to time $t$
De Finetti’s problem

Let assume that $X_t \rightarrow \infty$ a.s.

Controlled process:

$$U_t^\pi = X_t - D_t^\pi$$

where $D_t^\pi$ denotes cumulative amount of dividends transferred up to time $t$

$\tau^\pi$ - moment when the insurance company is wound up (then $U_{\tau^\pi}^\pi = 0$)
De Finetti’s problem

Let assume that $X_t \to \infty$ a.s.

Regulated process:

$$U^\pi_t = X_t - D^\pi_t$$

where $D^\pi_t$ denotes cumulative amount of dividends transferred up to time $t$

$\tau^\pi$ - moment when the insurance company is wound up (then $U^\pi_{\tau^\pi} = 0$)

$$\pi = (\tau^\pi, D^\pi_t)$$ - “dividend-liquidation” policy

is a pair of a non-decreasing left-continuous $\mathcal{F}$-adapted process $D^\pi_t$ and an $\mathcal{F}$-stopping time $\tau^\pi$. 
Let assume that $X_t \to \infty$ a.s.

Regulated process:

$$U^\pi_t = X_t - D^\pi_t$$

where $D^\pi_t$ denotes cumulative amount of dividends transferred up to time $t$

$\tau^\pi$ - moment when the insurance company is wound up (then $U^\pi_{\tau^\pi} = 0$)

$$\pi = (\tau^\pi, D^\pi_t)$$ - "dividend-liquidation" policy

is a pair of a non-decreasing left-continuous $\mathbb{F}$-adapted process $D^\pi_t$ and an $\mathbb{F}$-stopping time $\tau^\pi$.

We observe process $U^\pi_t$ up to $\tau^\pi \wedge \sigma^\pi$, where

$$\sigma^\pi = \inf\{t \geq 0 : U^\pi_t < 0\}$$
We assume that for $t < \sigma^\pi$

$$\Delta D_t^\pi := D_{t^+}^\pi - D_t^\pi < U_t^\pi$$

When dividends are being paid it could be added fixed transaction cost $K > 0$ that are not transferred to the beneficiaries (case $K = 0$ means no transactions costs). In this case we assume additionally that:

$$\Delta D_t^\pi \geq K$$

In this case $\pi$ is given by an increasing sequence $0 \leq T_1 \leq T_2 \leq \ldots$ of $\mathcal{F}$-stopping times representing the times at which a dividend payment is made and a sequence of positive $\mathcal{F}_{T_i}$-measurable random variables $J_i \geq K$ representing the sizes of the dividend payments. Then,

$$D_t^\pi = \sum_{k=1}^{N_t^\pi} J_k$$

where $N_t^\pi = \#\{k : T_k \leq t\}$
cumulative discounted dividends received until the moment of ruin:

\[ D_\pi(x) = \mathbb{E}_x \left[ \int_0^{\sigma_\pi \wedge \tau_\pi} e^{-qt}(dD_t^\pi - K)_+ \right] \]

where

\[ \int_0^t (dD_s^\pi - K)_+ = \begin{cases} D_t^\pi & \text{if } K = 0, \\ \sum_{s \leq t} 1\{\Delta D_t^\pi > K\}(\Delta D_t^\pi - K) & \text{if } K > 0 \end{cases} \]

and \( \mathbb{E}_x \) denotes expectation when \( X_0 = x \).
cumulative discounted dividends received until the moment of ruin:

\[ D_\pi(x) = \mathbb{E}_x \left[ \int_0^{\sigma_\pi \land \tau_\pi} e^{-qt}(dD_\pi^t - K)_+ \right] \]

where

\[ \int_0^t (dD_\pi^s - K)_+ = \begin{cases} D_\pi^t & \text{if } K = 0, \\ \sum_{s \leq t} 1_{\{\Delta D_\pi^s > K\}} (\Delta D_\pi^s - K) & \text{if } K > 0 \end{cases} \]

and \( \mathbb{E}_x \) denotes expectation when \( X_0 = x \).

Gerber-Shiu penalty/reward function:

\[ \mathcal{W}_w^\pi(x) = \mathbb{E}_x \left[ e^{-q(\sigma_\pi \land \tau_\pi)} w(U_\sigma_\pi \land \tau_\pi) \right] \]

where \( w \) is a penalty/reward function (for simplicity we assume that \( w(0) = 0 \))
• cumulative discounted dividends received until the moment of ruin:

\[ D_\pi(x) = \mathbb{E}_x \left[ \int_0^{\sigma_\pi \land \tau_\pi} e^{-qt}(dD_t^\pi - K)_+ \right] \]

where

\[ \int_0^t (dD_s^\pi - K)_+ = \begin{cases} D_t^\pi & \text{if } K = 0, \\ \sum_{s \leq t} 1_{\{\Delta D_s^\pi > K\}}(\Delta D_s^\pi - K) & \text{if } K > 0 \end{cases} \]

and \( \mathbb{E}_x \) denotes expectation when \( X_0 = x \).

• Gerber-Shiu penalty/reward function:

\[ \mathcal{W}_w^\pi(x) = \mathbb{E}_x \left[ e^{-q(\sigma_\pi \land \tau_\pi)}w(U_{\sigma_\pi \land \tau_\pi}^\pi) \right] \]

where \( w \) is a penalty/reward function (for simplicity we assume that \( w(0) = 0 \))

Value function:

\[ \nu_\pi(x) = D_\pi(x) + \mathcal{W}_w^\pi(x) \]
We want to find policy

\[ \pi^* = (\tau^*, D^*) \]

that maximizes

\[ v_\pi(x) = \mathbb{E}_x \left[ \int_0^{\sigma^* \wedge \tau^*} e^{-qt} (dD_t^\pi - K)_+ \right] + \mathbb{E}_x \left[ e^{-q(\sigma^* \wedge \tau^*)} w(U_{\sigma^* \wedge \tau^*}) \right] \]

Then

\[ v_*(x) = \sup_{\pi} v_\pi(x) = v_{\pi^*}(x) \]
Barrier strategy $\pi_a$ for $K = 0$
'If the barrier is too high, then we will wait too long for the risk process to hit the barrier and if we put the barrier too low then we derive the ruin too quickly.' We can then expect the existence of the 'optimal barrier'.
Local time at maximum

For the barrier strategy at \( a \) and for \( K = 0 \):

\[
D_t^{\pi_a} = a \lor \overline{X}_t - a, \quad \text{where } \overline{X}_t = \sup_{s \leq t} X_s
\]

and

\[
\{ U_t^{\pi_a}, t \leq \sigma^{\pi_a}; U_0^{\pi_a} = x \} \overset{D}{=} \{ a - Y_t, t \leq \sigma; Y_0 = a - x \}
\]

where

\[
Y_t = (a \lor \overline{X}_t) - X_t
\]

is reflected process at maximum and

\[
\sigma_a = \inf\{ t > 0 : Y_t > a \}
\]

is the first exit time of \( Y \) from interval \([0, a]\).
Controlled process once again

\[ \pi_a^{U_t} \]
Discounted local time
Bivariate subordinator

\[ D^{\pi_a}(x) = \int_0^{\sigma_a} e^{-qt} dD^\pi_t = \int_0^\infty e^{-qD^{\pi_a,-1}_t} \mathbf{1}_{(\sup_{s \leq t} \bar{\epsilon}_s \leq a)} dt \]

\[ = \int_0^\infty e^{-q\xi_t} \mathbf{1}_{(\sup_{s \leq t} \Delta\eta_s \leq a)} dt \]

where \( \Delta\eta_t = \eta_t - \eta_{t-} \) and \( (\xi, \eta) = \{ (\xi_t, \eta_t) : t \geq 0 \} \) is a bivariate subordinator.
\[ D^{\pi_a}(x) = \int_0^{\sigma_a} e^{-qt} dD_t^{\pi_a} = \int_0^\infty e^{-qD_t^{\pi_a,-1}} 1_{(\sup_{s\leq t} \bar{\epsilon}_s \leq a)} dt \]

= \int_0^\infty e^{-q\xi_t} 1_{(\sup_{s\leq t} \Delta \eta_s \leq a)} dt

where \( \Delta \eta_t = \eta_t - \eta_{t-} \) and \( (\xi, \eta) = \{(\xi_t, \eta_t) : t \geq 0\} \) is a bivariate subordinator

Theorem 1. (Kyprianou and Palmowski (2007)) For \( n = 1, 2, 3, \ldots \) we have:

\[ \mathbb{E} \left[ \left( \int_0^\infty e^{-q\xi_t} 1_{(\sup_{s\leq t} \Delta \eta_s \leq a)} dt \right)^n \right] = n! \prod_{k=1}^n \frac{1}{\Lambda(qk) + \nu_{\Lambda(qk)}(a, \infty)} \]

where \( \Lambda(q) \) is a Laplace exponent of \( \xi \) and \( \nu_{\Lambda(q)} \) is a Lévy measure of \( \eta \) under the change of measure:

\[ \frac{d\mathbb{P}^{\Lambda(q)}_t}{d\mathbb{P}_t} = e^{\Lambda(q)t-q\xi_t} \]
Barrier strategy $\pi_a$ for $K = 0$

$\mathcal{W}^\pi_w(x) = \mathbb{E}_x \left[ e^{-q\sigma\pi_a} w(U_{\sigma\pi_a}^{\pi_a}) \right]$
Barrier strategy $\pi_a$ for $K = 0$

$$\mathcal{W}^\pi_a(x) = \mathbb{E}_x \left[ e^{-q\sigma^\pi_a} w(U^\pi_a_{\sigma^\pi_a}) \right]$$

$$= \mathbb{E}_x \left[ \sum_{t \geq 0} e^{-qt} w(U^\pi_a_{t} + \Delta X_t) 1_{\{t < \sigma^\pi_a, \Delta X_t < U^\pi_a_t\}} \right]$$

$$= \int_0^a \int_y^\infty w(y - z) \Pi_X (dz) R^{(q)}(x, dy) = \int_0^a K_w(y) R^{(q)}(x, dy)$$

where $R^{(q)}(x, dy)$ is the resolvent of reflected at maximum process $Y$ killed when exiting from the interval $[0, a]$

$$R^{(q)}(x, dy) = \int_0^\infty e^{-qt} \mathbb{P}_x (Y_t \in dy, t < \sigma_a) dt$$

$$= \left[ \frac{W^{(q)}(x)}{W^{(q)'(a)}} W^{(q)'(a - y)} - W^{(q)}(x - y) \right] dy$$

$$+ \frac{W^{(q)}(x)}{W^{(q)'(a)}} W^{(q)}(0) \delta_a(dy)$$
Laplace exponent: $\psi(\theta)$:

$$\mathbb{E}[e^{\theta X_t}] = e^{t\psi(\theta)}$$

$\Phi(q)$ - greatest root of equation $\psi(\theta) = q$

First scaling function: $W^{(q)} : [0, \infty) \rightarrow [0, \infty)$:

$$\int_0^\infty e^{-\theta x} W^{(q)}(y) dy = (\psi(\theta) - q)^{-1}, \quad \theta > \Phi(q)$$

$W^{(q)}$ is differentiable (not necessary continuously) and

$$W(x) = W^{(0)}(x)$$

Second scaling function:

$$Z^{(q)}(y) = 1 + q \int_0^y W^{(q)}(z) \, dz$$
Barrier strategy $\pi_a$ for $K > 0$
Barrier-liq. strategy $\pi_{b,a}$, $K > 0$

$\pi_{b,a}$ for $a = (a_-, a_+)$ and $b > 0$
Barrier-liq. strategy $\pi_{b,a}$, $K = 0$

$\pi_{b,a}$ for $a > b$ and $b > 0$ ('limiting case' when $a_+ = a_- = a$)

For simplicity we will use the same notation $\pi_{b,a}$ for both cases.
Value function for $\pi_{b,a}$

Define:

\[ \tilde{w}(x) = w(x - b), \quad K_{\tilde{w}}(y) = \int_{-\infty}^{-y} \tilde{w}(y + z)\Pi_X(dz) < \infty \]

\[ F_{\tilde{w}}(x) = -\int_{0}^{x} W^{(q)}(x - y)K_{\tilde{w}}(y)dy \]
Define:

\[ \tilde{w}(x) = w(x - b), \quad K_{\tilde{w}}(y) = \int_{-\infty}^{-y} \tilde{w}(y + z) \Pi_X(dz) < \infty \]

\[ F_{\tilde{w}}(x) = -\int_{0}^{x} W^{(q)}(x - y) K_{\tilde{w}}(y) dy \]

**Theorem 2.** (Avram, Palmowski and Pistorius (2013))

\[ v_{\pi_{b,a}} := v_{b,a}(x) = \begin{cases} 
  w(x) & x < b \\
  W^{(q)}(x - b) G_b(a) + F_{\tilde{w}}(x - b) & x \in [b, a_+] \end{cases} \]

where

\[ G_b(a) := \begin{cases} 
  \frac{[\Delta a - K - \Delta F_{\tilde{w}}(a - b)]}{\Delta W^{(q)}(a - b)} & \text{if } K > 0 \\
  \frac{1 - F'_{\tilde{w}}(a - b)}{W^{(q)'}(a - b)} & \text{if } K = 0 \end{cases} \]

and \( \Delta a = a_+ - a_-, \quad \Delta g(a - b) = g(a_+ - b) - g(a_- - b) \).
We choose optimal barriers $a^* = (a_-, a_+)$ and $b^*$ (for $K = 0$: $a^* = a_+ = a_-$).

Let:

$$\mathcal{I}^*_w := \sup_{x > 0} \mathcal{I}_w(x), \quad \mathcal{I}_w(x) = \Gamma w(x) - qw(x)$$

where

$$\Gamma f(x) = \frac{\sigma^2}{2} f''(x) + pf'(x) + \int_{-\infty}^0 \left[ f(x + y) - f(x) - f'(x)y 1_{\{|y| < 1\}} \right] \Pi_X(dy)$$
We choose optimal barriers \( a^* = (a^*_-, a^*_+) \) i.e. \( b^* \) (for \( K = 0 \): \( a^* = a^*_- = a^*_+ \)).

Let:

\[
\mathcal{I}^*_w := \sup_{x > 0} \mathcal{I}_w(x), \quad \mathcal{I}_w(x) = \Gamma w(x) - qw(x)
\]

where

\[
\Gamma f(x) = \frac{\sigma^2}{2} f''(x) + pf'(x) + \int_{-\infty}^{0} \left[ f(x + y) - f(x) - f'(x)y \mathbf{1}_{\{|y| < 1\}} \right] \Pi_X(dy)
\]

**Theorem 3.** (APP (2013))

(i) If \( \mathcal{I}^*_w \leq 0 \), then it is optimal to stop immediately for all levels \( x > 0 \) of the reserves \( (\tau_* \equiv 0) \).

Assume that \( \mathcal{I}^*_w > 0 \). Then

(ii) \( \pi_{b^*, a^*} \) is the optimal strategy in the set of optimal strategies bounded by \( a^*_+ \);

(iii) if \( (\Gamma v_{b^*, a^*} - qv_{b^*, a^*})(x) \leq 0 \) for \( x > a^*_+ \), then \( \pi_{b^*, a^*} \) is optimal strategy and \( \nu_* = v_{b^*, a^*} \). In particular, if Lévy measure admits a convex density then barrier-liquidation strategy is optimal.
The proof of Theorem 3 is based in verification theorem which says that optimal value function should satisfies HJB system:

\[
\begin{align*}
\Gamma f(x) - q f(x) & \leq 0 \\
f(x) & \geq f(y) + x - y - K \\
f(x) & = w(x), \quad \text{for } x < 0 \\
f(x) & \geq w(x), \quad \text{for } x \geq 0
\end{align*}
\]
The proof of Theorem 3 is based in verification theorem which says that optimal value function should satisfies HJB system:

$$
\Gamma f(x) - qf(x) \leq 0
$$

$$
f(x) \geq f(y) + x - y - K
$$

$$
f(x) = w(x), \quad \text{for } x < 0
$$

$$
f(x) \geq w(x), \quad \text{for } x \geq 0
$$

In the proof we construct in fact new martingales, e.g for the first exit time

$$
T_{b,a} = \inf \{ t \geq 0 : X_t \notin [b, a] \}
$$

from interval $[b, a]$ processes:

$$
e^{-q(t \wedge T_{b,a})} W(q) \left( X_{t \wedge T_{b,a}} - b \right)
$$

$$
e^{-q(t \wedge T_{b,a})} F_{\bar{w}} \left( X_{t \wedge T_{b,a}} - b \right)
$$

are martingales
For \( w(x) = \sum_{m=0}^{k} a_m x^m \) we have

\[
F_{\tilde{w}}(x) = \sum_{m=0}^{k} a_m F_m(x - b)
\]

where \( F_0(x) = Z(q)(x) \) and for \( k \geq 1 \):

\[
F_k(x) = x^k + q \overline{W}^{(q,k)}(x) - \sum_{m=1}^{k} \binom{k}{m} \psi^{(m)}(0) \overline{W}^{(q,k-m)}(x)
\]

and

\[
\overline{W}^{(q,m)}(x) = \int_0^x (x - y)^m W(q)(y) dy
\]
For \( w(x) = \sum_{m=0}^{k} a_m x^m \) we have

\[
F_{\tilde{w}}(x) = \sum_{m=0}^{k} a_m F_m(x - b)
\]

where \( F_0(x) = Z^{(q)}(x) \) and for \( k \geq 1 \):

\[
F_k(x) = x^k + q \overline{W}^{(q,k)}(x) - \sum_{m=1}^{k} \binom{k}{m} \psi^{(m)}(0) \overline{W}^{(q,k-m)}(x)
\]

and

\[
\overline{W}^{(q,m)}(x) = \int_{0}^{x} (x - y)^m W(q)(y) dy
\]

If \( w(0) \neq 0 \), then instead of \( F_{\tilde{w}} \) we should take:

\[
Q(x) = F_{\tilde{w}}(x) + w(0) \frac{\sigma^2}{2} W^{(q)''}(x - b)
\]
Cramér-Lundberg process with Gamma claims:

\[ F(dx) = xe^{-x} dx, \]

discount intensity \( q = 0.1 \), Poisson intensity \( \lambda = 10 \),
premium rate \( p = 2(1 + 0.07)\lambda \).

Then:

\[ v^*(x) = \begin{cases} 
  x + 2.119 & x \in [0, 1.803) \\
  0.0944e^{-1.4882x} - 9.431e^{-0.07953x} + 11.257e^{-0.03957x} & x \in [1.803, 10.22) \\
  x + 2.456 & x \geq 10.22
\end{cases} \]
Band strategy $\pi_{b,a}$
Theorem 4. (APP (2013)) Let $K = 0$. For $i \geq 1$ and $v_{b,a} := v_{b,a}(x)$:

$$v_{b,a}(x) = \begin{cases} 
W^{(q)}(x - b_{i-1}) G_{w_{i-1}}(a_i, b_{i-1}) + F_{w_{i-1}}(x - b_{i-1}) & x \in [b_{i-1}, a_i) \\
v_{b,a}(a_{i-}) + x - a_i & x \in [a_i, b_i) 
\end{cases}$$

where

$$F_{w_{i-1}}(x - b_{i-1}) = w'_{i-1}(b_{i-1}) F_1(x) + w_{i-1}(b_{i-1}) F_0(x) + F_{w_{i-1,0}}(x)$$

and

$$w_{i-1,0}(x) = v_{b,a}(x - b_{i-1}) - v_{b,a}(b_{i-1}) - (x - b_{i-1}) v_{b,a}(b_{i-1})$$
Optimal bands:

- $a^*_i$ is determined by smooth fit condition of singular control:
  \[
  0 = \lim_{x \downarrow a^*_i} v''_{a^*,b^*}(x) = \lim_{x \uparrow a^*_i} v''_{a^*,b^*}(x),
  \]

- $b^*_i > 0$ is determined by smooth fit condition:
  \[
  1 = \lim_{x \uparrow b^*_i} v'_{a^*,b^*}(x) = \lim_{x \downarrow b^*_i} v'_{a^*,b^*}(x)
  \]

if $X$ has unbounded variation and determined by the continuous fit condition:

\[
\lim_{x \uparrow b^*_i} v_{a^*,b^*}(x) = \lim_{x \downarrow b^*_i} v_{a^*,b^*}(x)
\]

if $X$ has bounded variation.
Optimal bands:

\( a_i^* \) is determined by **smooth fit condition** of singular control:

\[
0 = \lim_{x \downarrow a_i^*} v''_{a_i^*, b_i^*}(x) = \lim_{x \uparrow b_i^*} v''_{a_i^*, b_i^*}(x),
\]

\( b_i^* > 0 \) is determined by **smooth fit condition**:

\[
1 = \lim_{x \uparrow b_i^*} v'_{a_i^*, b_i^*}(x) = \lim_{x \downarrow b_i^*} v'_{a_i^*, b_i^*}(x)
\]

if \( X \) has unbounded variation and determined by the **continuous fit condition**:

\[
\lim_{x \uparrow b_i^*} v_{a_i^*, b_i^*}(x) = \lim_{x \downarrow b_i^*} v_{a_i^*, b_i^*}(x)
\]

if \( X \) has bounded variation.

**Theorem 5.** (APP (2013)) Band strategy \( \pi_{b_i^*, a_i^*} \) is always optimal.
Let

$$X_t = x + pt - \sum_{k=1}^{N_t} C_k$$

where $C_k = \text{Exp}(\mu)$. 
Let

\[ X_t = x + pt - \sum_{k=1}^{N_t} C_k \]

where \( C_k = \text{Exp}(\mu) \). Then

\[ W(q)(x) = p^{-1} \left( A_+ e^{q^+(q)x} - A_- e^{q^-(q)x} \right), \]
\[ Z(q)(x) = p^{-1} q \left( q^+(q)^{-1} A_+ e^{q^+(q)x} - q^-(q)^{-1} A_- e^{q^-(q)x} \right) \]

where \( A_\pm = \frac{\mu + q^\pm(q)}{q^+(q) - q^-(q)} \) and \( q^+(q) = \Phi(q) \) and \( q^-(q) \) solve equation \( \psi(\theta) = q \):

\[ q^\pm(q) = \frac{q + \lambda - \mu p \pm \sqrt{(q + \lambda - \mu p)^2 + 4pq\mu}}{2p} \]
Let
\[ X_t = x + pt - \sum_{k=1}^{N_t} C_k \]
where \( C_k = \text{Exp}(\mu) \). Then
\[ W^{(q)}(x) = p^{-1} \left( A_+ e^{q_+^{(q)}x} - A_- e^{q_-^{(q)}x} \right), \]
\[ Z^{(q)}(x) = p^{-1} q \left( q_+^{(q)} A_+ e^{q_+^{(q)}x} - q_-^{(q)} A_- e^{q_-^{(q)}x} \right) \]
where \( A_\pm = \frac{\mu + q_\pm^{(q)}}{q_+^{(q)} - q_-^{(q)}} \) and \( q_+^{(q)} = \Phi(q) \) and \( q_-^{(q)} \) solve equation \( \psi(\theta) = q \):
\[ q_\pm^{(q)} = \frac{q + \lambda - \mu p \pm \sqrt{(q + \lambda - \mu p)^2 + 4pq\mu}}{2p} \]
Let consider piecewise-linear Gerber-Shiu function:
\[ w(x) = cx \mathbf{1}_{\{x<0\}} + (x - K) \mathbf{1}_{\{x>0\}} \]
Liquidation strategy is optimal when:

\[ \mathcal{I}_w^* \leq 0 \]

\[ \iff \]

\[ c \geq \max \{ c_1, c_2 \} \]

where

\[ c_1 = (p\mu/\lambda + K(\mu + \frac{q\mu}{\lambda})) \]

\[ c_2 = 1 + K\mu + \frac{q}{\lambda} \exp \left\{ \left( \frac{p\mu - \lambda}{q} + K\mu - 1 \right)_+ \right\} \]

If \( c \in [c_1, c_2) \), then barrier-liquidation strategy \( \pi_{b^*,a^*} \) with \( b^* > 0 \) is optimal.

If \( c < \min \{ c_1, c_2 \} \), then barrier strategy \( \pi_{a^*} \) is optimal (hence \( b^* = 0 \)).
Parisian barrier strategy $\pi_a$
Everything remains the same if one takes (Czarna and Palmowski (2013)):

\[ V^{(q)}(x) = e^{\Phi(q)x} \mathbb{P}_x^{\Phi(q)}(\tau^\xi = \infty), \]

instead of \( W^{(q)}(x) \), where

\[ \tau^\xi = \inf\{t > 0 : t - \sup\{s \leq t : X_s \geq 0\} \geq \xi, X_t > 0\} \]

**Theorem 6.** (Czarna and Palmowski (2011), Loeffen, Czarna, Palmowski (2013)) For \( x \geq 0 \):

\[
\mathbb{P}_x(\tau^\xi < \infty) = 1 - \mathbb{E}X_1 \frac{\int_0^\infty W(x + z)z\mathbb{P}(X_\xi \in dz)}{\int_0^\infty z\mathbb{P}(X_\xi \in dz)}
\]
If

\[ X_t = x + pt - \sum_{k=1}^{N_t} C_k \]

where \( C_k = \text{Exp}(\mu) \), then

\[ \mathbb{P}_x(\tau^\zeta < \infty) = e^{(\frac{\lambda}{p} - \mu)x} \left( 1 - \frac{p\mu - \lambda}{e^{-\lambda\zeta} p\mu + e^{-\lambda\zeta} \frac{\mu}{\zeta} D_2} \right) \]

for

\[ D_2 = \int_0^{p\zeta} (p\zeta - t)e^{-\mu t} \sqrt{\frac{\mu \lambda \zeta}{t}} I_1(2\sqrt{t\mu \lambda \zeta}) dt \]
We take the following parameters:

\[ w(x) = 0 \text{ for } x \leq 0, \mu = 2, \lambda = 2, q = 0.1, p = 2.5. \]

Then

\[ a^* = 3.78. \]

Table 3: How much more initial capital is required to have the same amount of dividend payments for classical and Parisian ruin.
Brownian motion with drift

\[ X_t = x + \sigma B_t + pt \]

For \( x \geq 0 \)

\[
\mathbb{P}_x(\tau^\zeta < \infty) = e^{-(2p\sigma^{-2})x} \frac{\Xi \left( \frac{p}{\sigma} \sqrt{\frac{\zeta}{2}} \right) - \frac{p}{\sigma} \sqrt{\frac{\zeta \pi}{2}}}{\Xi \left( \frac{p}{\sigma} \sqrt{\frac{\zeta}{2}} \right) + \frac{p}{\sigma} \sqrt{\frac{\zeta \pi}{2}}} 
\]

where

\[
\Xi(x) = 2\sqrt{\pi} x \mathcal{N}(\sqrt{2}x) - \sqrt{\pi} x + e^{-x^2}
\]

and \( \mathcal{N}(\cdot) \) is a distribution function of standard normal random variable.
Brownian motion with drift

Let

\[ X_t = \sigma B_t + pt \]

Then:

\[ W^{(q)}(x) = \frac{1}{\sigma^2 \delta} [e^{(-\omega+\delta)x} - e^{-(\omega+\delta)x}] \]

where

\[ \delta = \sigma^{-2} \sqrt{p^2 + 2q\sigma^2} \]

and

\[ \omega = p/\sigma^2 \]
Brownian motion with drift

\[ a^* = \log \left| \frac{\delta + \omega}{\delta - \omega} \right|^{1/\delta} \]

for \( \delta = \sigma^{-2} \sqrt{p^2 + 2q\sigma^2} \) and \( \omega = p/\sigma^2 \) and

\[ a^*,\zeta = \frac{\sigma^2}{pq} \log \left[ \frac{\Psi \left( \frac{pq}{\sigma} \sqrt{\frac{\zeta}{2}} \right) - \frac{pq}{\sigma} \sqrt{\frac{\zeta\pi}{2}}}{\Psi \left( \frac{pq}{\sigma} \sqrt{\frac{\zeta}{2}} \right) + \frac{pq}{\sigma} \sqrt{\frac{\zeta\pi}{2}}} \left( 1 - \frac{2pq}{pq - p} \right) \right] \]

for

\[ \Psi(x) = 2\sqrt{\pi}xN(\sqrt{2}x) - \sqrt{\pi}x + e^{-x^2} \]

and

\[ pq = \sqrt{p^2 + 2q\sigma^2} \]
We take the following parameters: \( w(x) = 0 \) for \( x \leq 0 \), \( \sigma = 2 \), \( p = 2.5 \). Then

\[
a^* = 5.28.

Table 6: How much more initial capital is required to have the same amount of dividend payments for classical and Parisian ruin.
Albrecher, Cheung and Thonhauser (2013) consider classical risk process and look at this process only at random observation times \( \{T_k\} \) at which a lump sum dividend payment of size \( x - b \) will take place if the current surplus level \( x \) exceeds the barrier level \( b \) (’discrete’ version of the barrier strategy) and the process will be declared ruined if \( x < 0 \). Authors derive the integro-differential equation for the value function.
Harrison and Taylor SPA 6 1978 and Løkka and Zervos 2005 (for the Brownian motion)

\[ \pi = \{ L_t^\pi, R_t^\pi, t \geq 0 \} \]

non-decreasing \( \mathbb{F} \)-adapted processes describing the cumulative amount of paid dividends and cumulative amount of injected capital

The controlled risk process:

\[ V_t^\pi = X_t - L_t^\pi + R_t^\pi \]

Value function:

\[ \bar{\nu}_*(x) = \sup_{\pi} \mathbb{E}_x \left[ \int_0^\infty e^{-qt} dL_t^\pi - \varphi \int_0^\infty e^{-qt} dR_t^\pi \right] \]

where \( \varphi > 1 \) is the cost per unit injected capital
Optimal policy

\[ \overline{v}_a(x) = \begin{cases} 
\varphi(\overline{Z}^{(q)}(x) + \psi'(0^+)/q) + Z^{(q)}(x) \left[ \frac{1-\varphi Z^{(q)}(a)}{qW^{(q)}(a)} \right] & 0 \leq x \leq a, \\
 x - a + \overline{v}_a(a) & x > a 
\end{cases}\]

where

\[ \overline{Z}^{(q)}(y) = \int_0^y Z^{(q)}(z)dz = y + q \int_0^y \int_0^z W^{(q)}(w)dw dz \]

Theorem 7 (Avram, Palmowski and Pistorius (2007)) Optimal strategy is a barrier strategy with the barrier

\[ d^* = \inf \{ a > 0 : G(a) \leq 0 \} \]

where \( G(a) := [\varphi Z^{(q)}(a) - 1]W^{(q)'}(a) - \varphi qW^{(q)}(a)^2 \)
Scheer and Schmidli (2011), Kulenko and Schmidli (2008) maximise the discounted dividend payments minus the penalised discounted capital injections. Authors derive the Hamilton-Jacobi-Bellman equation for the problem and show that the optimal strategy is a barrier strategy.
DCF pricing

DCF - Discounted Cash Flow (Gajek and Kuciński (2011), only for Cramér-Lundberg process)

Value function:

$$\overline{v}_*(x) = \sup_{\pi, \sigma} \mathbb{E}_x \left[ \int_0^\sigma e^{-qt} dL_t^\pi - \varphi \int_0^\sigma e^{-qt} dR_t^\pi \right]$$

Under classical assumptions the optimal strategy is to keep risk process non-negative until the first jump below level $-b < 0$

Pricing PZU This method produces price 8,03 bn EUR, the true market price in 2010 was: 7,97 bn EUR
Process $U$ solves equation:

$$U_t = X_t - \delta \int_0^t 1_{\{U_s > a\}} \, ds$$

Discounted cumulant dividends (Kyprianou and Loeffen (2010) and Gerber and Shiu (2006)):

$$E_x \int_0^{\sigma_a} e^{-qt} 1_{\{U_s > a\}} \, ds = -\int_0^{0 \wedge (x-a)} W^{(q)}(z) \, dz$$

$$+ \frac{W^{(q)}(x) + \delta 1_{\{x > a\}} \int_x^a W^{(q)}(x-y) W^{(q),'}(y) \, dy}{\phi(q) \int_0^\infty e^{-\phi(q)y} W^{(q),'}(y+a) \, dy}$$

where

$$\phi(q) = \sup\{\psi(\theta) - \delta \theta = q\}$$

and $W^{(q)}$ and $Z^{(q)}$ are the scale function associated with process $X_t - \delta t$
The process $U^\gamma$ models the surplus process of an insurance company that pays out taxes according to a loss-carried-forward tax scheme, using a surplus-dependent rate $\gamma(\cdot)$. In other words, tax are collected when the company has recovered from its previous losses, i.e., is in a so-called profitable situation. Finally, note that when $\gamma(\cdot) = \gamma \in [0, 1]$, this model amounts to the situation studied in Albrecher et al. (2008) where the tax rate is constant, and when $\gamma = 1$, we retrieve the model where the company pays out as dividends any capital above its initial value $U^\gamma = x$ as in a risk model with a horizontal barrier strategy at level $u$ (see e.g. Renaud and Zhou (2007)). Then:

$$E_x \int_0^{\sigma^a} e^{-qt} \gamma(\overline{X}_s) d\overline{X}_s = \int_x^{\infty} \exp \left\{ - \int_x^t \frac{W(q,')(\gamma(s))}{W(q)(\gamma(s))} ds \right\} \gamma(t) \, dt$$

where $\overline{\gamma}(y) = y - \int_x^y \gamma(s) \, ds$
Utility function

\[ U_t^\pi = X_t - \int_0^t c_s \, ds \]

Value function:

\[ v(x) = \sup \mathbb{E} \left( \int_0^\infty e^{-qt} m(c_t) \, dt \right) \]

for utility function \( m \), e.g. for:

\[ m(x) = \frac{x^\alpha}{\alpha}, \quad \alpha \in (0, 1) \]

Assume that the optimal strategy \( c^* \) is a function \( c^* \) of preset reserves. Then:

\[ c^*(x) = (m')^{-1}(v_x) \]
For $m(x) = \frac{x^\alpha}{\alpha}$ the value function solves the following differential equation:

$$pv_{xx} + (\mu p - q - \lambda)v_x - \mu q v + \mu \frac{1 - \alpha}{\alpha} v_x^{\frac{-\alpha}{1-\alpha}} - v_x^{\frac{-1}{1-\alpha}} v_{xx} = 0$$

$$v(0) = \frac{p}{q + \lambda} v_x(0) + \frac{1 - \alpha}{\alpha(q + \lambda)} v_x(0)^{\frac{-\alpha}{1-\alpha}}$$
Theorem 8. (Baran and Palmowski (2013)) For large initial capital $x$ we have:

\[
\begin{align*}
    v(x) & \sim \left( \frac{\alpha}{2\alpha - 1} \right) \left( \frac{1 - \alpha}{\alpha \beta} \right)^{1-\alpha} x^{2\alpha-1} \\
    v_{x}(x) & \sim \left( \frac{1 - \alpha}{\alpha q} \right)^{\frac{1-\alpha}{\alpha}} x^{-\frac{(1-\alpha)}{\alpha}} \\
    c^{*}(x) & \sim \left( \frac{1-\alpha}{\alpha q} \right)^{-\frac{1}{\alpha}} x^{\frac{1}{\alpha}}
\end{align*}
\]
Consider now a particular two-dimensional risk model in which two companies split the amount they pay out of each claim in fixed proportions (for simplicity we assume that they are equal), and receive premiums at rates $p_1$ and $p_2$, respectively (so-called proportional reinsurance). That is,

$$X_t = \left( X_1(t), X_2(t) \right) = \left( u_1 + p_1 t - \beta_1 \sum_{i=1}^{N_t} C_i, u_2 + p_2 t - \beta_2 \sum_{i=1}^{N_t} C_i \right).$$

Without loss of generality we will assume that $\beta_1 = \beta_2 = 1$ and $p_1 > p_2$. 

Two-dimensional risk process
Two-dimensional risk process

\[ u_1 = (-1, a) \]

\[ U(t) \]
Two-dimensional risk process

Controlled risk process:

\[ \bar{U}_t = (U_1(t), U_2(t)) = X_t - L_t \]

where

\[ L(t) = \left( \delta_1 \int_0^t 1_{\{U(t) \in B\}}, \delta_2 \int_0^t 1_{\{U(t) \in B\}} \right) \]

describes the two-dimensional linear drift at rate \( \bar{\delta} = (\delta_1, \delta_2) > (0, 0) \) which is subtracted from the increments of the risk process whenever it enter the fixed set:

\[ B = \{(x, y) : x, y \geq 0 \text{ and } y \geq b - ax\}, \quad a, b > 0. \]

The case \( \bar{\delta} = p - a \) for \( p = (p_1, p_2) \) and \( a = (-1, a) \) corresponds to the reflecting the risk process at the line \( y = b - ax \). Let

\[ v_n(u_1, u_2) = v_n(u) = \mathbb{E}_u \left[ (1, 1) \cdot \int_0^\sigma e^{-qt} dL(t) \right]^n \]

where \( \sigma = \inf\{t \geq 0 : U_1(t)U_2(t) < 0\} \)
Two-dimensional risk process

Theorem 9. (Czarna and Palmowski (2011))

\[ p \cdot \frac{\partial v_n}{\partial u}(u) - (\lambda + nq)v_n(u) + \lambda \int_0^{\min(u_1, u_2)} v_n(u - (1, 1)\nu) \, dF(\nu) = 0 \]

with the boundary conditions:

\[ n\delta_0 \, V_{n-1}(u) = \delta \cdot \left. \frac{\partial v_n}{\partial u} \right|_{u \in \mathcal{B}}, \quad u \in \mathcal{B} \]

\[ \lim_{b \to \infty} v_n(u) = 0, \quad u \in \mathcal{B}^c \]

\[ v_n(0, b) = 0 \]

where \( \delta_0 = \delta_1 + \delta_2 \)
Assume that we have $\text{Exp}(\mu)$ claims with $\mu = 2$ and that $p_1 = 4$, $p_2 = 3$, $\lambda = 1$, $q = 0.1$.

Note that always there exists optimal choice of linear barrier (choice of its upper left end $(0, b)$ and it slope $a$). This choice depends on the initial reserves $(u_1, u_2)$. For $(u_1, u_2) = (1, 2)$ the optimal barrier is determined by $b = 14$ and $a = 0.1$ and for $(u_1, u_2) = (2, 3)$ the optimal barrier is determined by $b = 15$ and $a = 0.1$. This is contrast to the one-dimensional case where the choice of the barrier is given only via the premium rate and the distribution of the arriving claims.
